The rheology of lower crust and upper mantle has been determined by deformation experiments of polycrystalline samples of rock-forming minerals. In these experiments, the samples were often synthesized to obtain fine-grained polycrystalline. In this study, we investigate a method for preparing the fine-grained polycrystalline clinopyroxene from nano-sized natural powders of clinopyroxene.

The starting materials for the experiment were prepared from two types of diopside single crystals (Di97Hed3:Ca_{0.99}Na_{0.01}Mg_{0.97}Fe_{0.03}Si₂O₆, Di99Hed1:Ca_{0.97}Na_{0.02}Mg_{0.86}Fe_{0.13}Si₂O₆) and a salite single crystal (Di87Hed13:Ca_{0.97}Na_{0.02}Mg_{0.86}Fe_{0.13}Al_{0.02}Si₂O₆). They were crushed and milled into nano-sized powders. The milled powders were uniaxially pressed and sintered at 1230 - 1280 °C in atmospheres of argon or vacuum for 2-6h. After the sintering, sample surfaces were polished and thermally etched to expose grain boundaries. Grain size and porosity were determined from the microstructure of scanning electron microscope (SEM).

After sintering at 1230°C, the relative density increased with increasing sintering time and reached the value of 98.0% and 93.5% of the theoretical density for Di97Hed3 and Di99Hed1 samples respectively. The grain size of the each sample remains about <2µm. On the other hand, only 94.1% and 90.5 vol% of theoretical density were obtained from samples sintered at 1280°C and the grain size increased to 5µm. Abnormally large grains and large porosities were found in Di87Hed13 sample. We found that the sintering temperature of 1230°C is more suitable for densification and grain growth of polycrystalline clinopyroxene than 1280°C.
