We analyzed temporal variation of ClO, ClONO\textsubscript{2}, HCl, HNO\textsubscript{3}, and O\textsubscript{3} measured by satellite sensors Aura/MLS, Envisat/MIPAS, and ground-based Fourier-Transform infrared spectrometer (FTIR) installed at Syowa Station, Antarctica (69.0S, 39.6E) from March to December, 2007 and September to November, 2011. Vertical profiles of O\textsubscript{3}, HNO\textsubscript{3}, and HCl and vertical column of ClONO\textsubscript{2} were retrieved from solar spectra taken with a ground-based FTIR. We analyzed temporal variation of these species at 18 and 22 km over Syowa Station. In early July, polar stratospheric clouds (PSCs) started to be formed over Syowa Station. With the return of sunlight at Syowa Station in early July, ClONO\textsubscript{2} and HCl showed depleted values while ClO showed enhanced values. At two altitudes (18 and 22 km), when ClO concentrations started to decline in early September, HCl started to increase rapidly, while the increase in ClONO\textsubscript{2} was gradual. The Cl\textsubscript{y} partitioning between HCl, ClONO\textsubscript{2}, and ClO showed difference at different altitudes. At the altitudes of 18 km, where ozone was almost depleted, ClO and HNO\textsubscript{3} amounts are low, so conversion to HCl was favored rather than ClONO\textsubscript{2}. Whereas, at 22 km, sufficient ozone still remained, at an amount that ClONO\textsubscript{2} formation from ClO and NO\textsubscript{y} species continued to occur at this altitude. In early winter, HCl depletion continued even when the counterpart of the heterogeneous reaction (ClONO\textsubscript{2}) disappeared. Possible cause of this depletion could be attributed by the mixing of vortex edge air where NO\textsubscript{y} is formed by photochemical reaction, and resulting ClONO\textsubscript{2} production, and gradual heterogeneous reaction with HCl.
