Phosphorus is thought to be an important light element existing in planetary cores. The phosphorus abundance is evaluated to be ~0.20 wt% in the Earth’s core, and ~0.32 wt% in the Martian core. To fully understand its existence in planetary cores, structural and physical properties of iron-nickel phosphides should be investigated under high pressure and high temperature. (Fe,Ni)$_3$P-schreibersite is observed as a common accessory in the veinlet of iron and stony-iron meteorites, so that it is of significance to discuss and constrain the properties of planetary cores. The equation of state of a natural single-crystal schreibersite, Fe$_{2.15}$Ni$_{0.85}$P, has been studied up to ~50 GPa at room temperature in a diamond anvil cell using in situ synchrotron-radiation X-ray diffraction. The sample kept its tetragonal structure (I-4) up to the highest pressure with no observation of phase transition. Experimental results have shown that the magnetic collapse of Fe$_{2.15}$Ni$_{0.85}$P is weakened because of the substitution of nickel, leading to an isotropic axial compressibility. The pressure-volume data were fitted by the third-order Birch-Murnaghan equation of state, yielding $K_0 = 184(4)$ GPa, $K'_0 = 4.1(2)$, $V_0 = 365.9(1)$ Å$^3$. The density of Fe$_{2.15}$Ni$_{0.85}$P, along with several iron sulfides and iron phosphides has been calculated under relative pressure-temperature conditions of the Martian core. The comparison with that of γ-Fe and a density model of the Martian core evidences that nickel and phosphorus dopant would result in density reduction of iron sulfides, suggesting that (Fe,Ni)$_3$(S,P) might be a possible compound existing in the Martian core.
