Seagrass meadows are one of the most productive ecosystems and play an important role as carbon reservoirs, storing large amount of organic carbon in the sediments. Estuaries are considered to be a net source of atmospheric CO$_2$ due to the mineralization of terrestrial carbon but recent studies demonstrated that seagrass meadows in estuaries can be sinks for atmospheric CO$_2$. The flow of organic and inorganic carbon derived from multiple sources regulates these processes but the knowledge about these relationships is limited. In this study, we evaluated the flow of carbon derived from multiple sources in seagrass meadows using isotopic approaches and associated the flow with the processes of both atmospheric CO$_2$ uptake and carbon storage in sediments. We estimated the contribution of atmospheric CO$_2$ to assimilated seagrass carbon by a carbon-source mixing model using radiocarbon concentrations ($\Delta^{14}$C). The model indicated that the seagrass assimilated 0–40% of its inorganic carbon as atmospheric CO$_2$. The stable isotopic signatures ($\delta^{13}$C and $\delta^{15}$N) of both particulate organic carbon (OC) and sedimentary OC suggested that the efficiency of OC storage in sediments would be dependent on OC derived from multiple sources. We will also present the historical changes in carbon storage using sediment core analyses.
