Selectively doped GaAs/n-AlGaAs heterostructures are grown by employing reduced pressure metal organic chemical vapor deposition. It is shown that the growth condition in an undoped Al0.3Ga0.7As layer has a remarkable effect on two dimensional electron gas (2DEG) mobility. A 2DEG mobility of 150,000 cm²/V·sec is obtained for a sample with electron concentration (N_e) of 6.9x10¹⁰ cm⁻² at 4.2K. The 2DEG mobility increases by more than an order in magnitude with increasing N_e as a result of exposure to light and reaches a maximum value of 180,000 cm²/V·sec at N_e = 7.8x10¹⁰ cm⁻².

(1) Introduction

Recently, selectively doped (SD) GaAs/n-AlGaAs heterostructures have become of major interest from the point of view of application to high-speed devices. This is because the two dimensional electron gas (2DEG) accumulating at the heterointerface has extremely high mobility. SD GaAs/n-AlGaAs heterostructures have conventionally been grown by Molecular Beam Epitaxy (MBE), and 2DEG mobility as high as 212,000 cm²/V·sec (at 5K) has been reported. These results show that MBE is a suitable growth method for obtaining abrupt heterointerfaces and doping profiles.

There have been several reports on SD GaAs/n-AlGaAs heterostructures grown by Metal Organic Chemical Vapor Deposition (MOCVD). However, MOCVD growth conditions for obtaining SD GaAs/n-AlGaAs heterostructures with high 2DEG mobility have not yet been clarified. In this paper, we describe the MOCVD growth apparatus and growth conditions for realizing high-performance 2DEG mobility. From these results, it is clear that the growth conditions for the undoped Al0.3Ga0.7As spacer layer, the ratio of arsine mole fraction to TMG, the organo-metallic compound mole fraction, has a considerable effect on 2DEG mobility.

(2) Experiment

O₂/H₂O contamination in the MOCVD growth of AlGaAs caused by an air leak in the MOCVD gas manifold or reactor system or by O₂/H₂O included in materials such as arsine (AsH₃), results in oxygen incorporation in AlGaAs. Oxygen doped AlGaAs results in a semi-insulating layer due to the formation of deep impurity levels. Therefore, in order to obtain stable n-type doping in AlGaAs, a leak-proof gas manifold and reactor system are minimum requirements. Moreover, abrupt heterointerfaces and doping profiles are considered to be necessary to obtain SD GaAs/n-AlGaAs heterostructures with high 2DEG mobility. For this purpose, a rapid change in the gas composition over the substrate is required.

The MOCVD growth apparatus was helium leak-tested to a rate of less than 10⁻⁸ atm·cc/sec, and the oxygen concentration in the hydrogen carrier gas flowing through the gas manifold and the reactor from the paraffin diffused hydrogen purifier was observed to
be less than 0.01 ppm. Figure 1 shows a schematic view of the reactor system in the MOCVD apparatus.

Epitaxial layers were grown in the water-cooled vertical reactor system composed of a 100 mm inner-diameter fused silica tube and a graphite susceptor. Substrates were put on the graphite susceptor having inclined planes of about 25° to the gas flow direction. This is done to prevent gas flow pattern disturbance. The susceptor was heated by RF induction and its temperature was measured by an infrared radiation thermometer.

Trimethyl gallium (TMG), trimethyl aluminum (TMA), arsine (AsH₃) and silane (SiH₄) were used as the Ga, Al, As and Si sources, respectively. A rapid change in gas composition over the substrate is required to obtain abrupt heterointerfaces and doping profiles. For this purpose, it is necessary to minimize the inside volume Va (the crosshatched region shown in Fig.1) and increase the total gas flow velocity over the substrate, (60 cm/sec for a total flow of 10 standard liters per minute under a reactor pressure of 80 Torr, which were the typical condition used here.) This reactor construction enabled the rapid change (within 0.1sec) of gas composition over the substrate. Cr-O doped semi-insulating substrates were used in the experiment. The substrate orientation was (100) tilted 2° toward (110). The growth temperature was 650°C and the growth rate was 4.0~12.0 Å/sec.

(3) Result and Discussion

3.1 Estimation of the abruptness in MOCVD growth GaAs/AlGaAs heterointerfaces

The abruptness of GaAs/Al₀.₃Ga₀.₇As heterointerfaces grown by MOCVD was estimated by using Auger Electron Spectroscopy (AES) and Ar⁺ ion sputtering. Figure 2 shows the composition depth profile of an epitaxial wafer with Al₀.₃Ga₀.₇As(500Å)/GaAs(5000Å) /GaAs substrate structure, having almost the same structure as SD heterostructures which will be described later. To obtain the exact abruptness of the GaAs/Al₀.₃Ga₀.₇As heterointerface, the thickness of the Al₀.₃Ga₀.₇As surface layer was measured with a field emission scanning electron microscope (x70000) and a low energy Auger signal (Al LVV line) was used because of the low escape depth (~5Å) of Auger electrons. The abruptness measured by using the Al LVV and Ga LMM lines are observed to be 10.5Å and 20.5Å, respectively. This difference in abruptness is considered to arise from the escape depth difference in Al LVV and Ga LMM Auger electrons. The real abruptness in a MOCVD growth GaAs/Al₀.₃ Ga₀.₇As heterostructure was assumed to be less than 6Å considering the Auger electron escape depth into the measured value. The very abrupt heterointerface was realized by the MOCVD growth apparatus used here.

3.2 Selectively doped GaAs/n-Al₀.₃Ga₀.₇As heterostructures

It has been reported that both the impurity concentration and the conduction type for MOCVD growth GaAs and AlGaAs layers depend on the ratio, θ, of the AsH₃ mole fraction to the III group organometallic compound mole fraction, [AsH₃]/[TMG] or [AsH₃] / [{TMG} + {TMA}]. In order to obtain SD GaAs/n-AlGaAs heterostructures with high 2DEG mobility by MOCVD, it is necessary to minimize the total impurity concentration in both the undoped GaAs and Al₀.₃Ga₀.₇As spacer layers, as it has a direct effect on 2DEG mobility due to ionized impurity scattering.

In this paper, the most suitable MOCVD growth condition for obtaining SD GaAs/n-Al₀.₃Ga₀.₇As heterostructures with high 2DEG mobility was determined by examining the effect of θ in both undoped GaAs and Al₀.₃Ga₀.₇As spacer layer growth on 2DEG mobility. SD heterostructures fabricated here have been measured by using the Al LVV and Ga LMM lines are observed to be 10.5Å and 20.5Å, respectively. This difference in abruptness is considered to arise from the escape depth difference in Al LVV and Ga LMM Auger electrons. The real abruptness in a MOCVD growth GaAs/Al₀.₃ Ga₀.₇As heterostructure was assumed to be less than 6Å considering the Auger electron escape depth into the measured value. The very abrupt heterointerface was realized by the MOCVD growth apparatus used here.

Fig.2 Composition depth profile of GaAs/AlGaAs heterostructure by using AES measurement.
the layer structure of Si doped n-Al\textsubscript{0.3}Ga\textsubscript{0.7}As(500Å) /undoped Al\textsubscript{0.3}Ga\textsubscript{0.7}As(100Å)/undoped GaAs(0.7~3μm)/semi-insulating GaAs substrate.

The conduction type, carrier concentration, and mobility of undoped GaAs layers grown at four \(T\) values (10, 28, 56 and 80) are shown in Table 1. The total impurity concentration in the undoped GaAs layer is considered to be minimum around the \(T\) value at which the conduction type changes from semi-insulating to n-type. Therefore, the most suitable growth condition for undoped GaAs in Si heterostructures is expected to be around \(T=56\) K.

An undoped Al\textsubscript{0.3}Ga\textsubscript{0.7}As spacer layer is inserted between the Si doped n-Al\textsubscript{0.3}Ga\textsubscript{0.7}As and undoped GaAs layer to increase 2DEG mobility. This layer weakens the scattering of 2DEG due to ionized impurities in the Si doped Al\textsubscript{0.3}Ga\textsubscript{0.7}As layer. Therefore, the growth condition for minimizing the total impurity concentration including the carbon acceptor, which becomes a serious problem in AlGaAs layer\textsuperscript{12}, is required to obtain high 2DEG mobility. Figure 3 shows the relation between 2DEG mobility at 77K and the \(T\) value for the growth of the undoped Al\textsubscript{0.3}Ga\textsubscript{0.7}As spacer layer, when \(N_e\) at 77K was fixed at \(8.0 \times 10^{11}\) cm\(^{-2}\). 2DEG mobility as high as 83000 cm\(^2\)/V·sec was obtained, and a remarkable increase in 2DEG mobility was observed when \(T\) was increased from 40 to 80 for the growth of the undoped AlGaAs spacer layer. The increase in 2DEG mobility is considered to be due to the decrease in the carbon acceptor in the Al\textsubscript{0.3}Ga\textsubscript{0.7}As spacer layer. On the other hand, the decrease in 2DEG mobility observed at \(T > 80\) is considered to be due to the increase in the donor concentration. As a result of this observation, the total impurity concentration in the undoped Al\textsubscript{0.3}Ga\textsubscript{0.7}As layer is assumed to be minimum at \(T = 80\) K.

Figure 4 shows the temperature dependence of both the sheet electron concentration and mobility for the SD GaAs/n-Al\textsubscript{0.3}Ga\textsubscript{0.7}As heterostructure with the highest mobility. 2DEG mobility at room temperature, 77K and 4.2K was 6800, 83000, and 150000 cm\(^2\)/V·sec, respectively.

Fig. 3 Relation between 2DEG mobility at 77K and value for undoped Al\textsubscript{0.3}Ga\textsubscript{0.7}As spacer layer growth, when \(N_e\) at 77K was fixed to \(8.0 \times 10^{11}\) cm\(^{-2}\).

Fig. 4 Temperature dependence of both sheet electron concentration and mobility for SD GaAs/n-Al\textsubscript{0.3}Ga\textsubscript{0.7}As heterostructure.

Fig. 5 Magnetoresistance measured at 4.2K as a function of the magnetic field applied perpendicular to the heterointerface for SD GaAs/n-Al\textsubscript{0.3}Ga\textsubscript{0.7}As heterostructure.

Magnetoresistance for the same sample as in Fig. 4 was measured at 4.2K as a function of the magnetic field applied perpendicular to the heterointerface. As shown in Fig. 5, Shubnikov De Haas
(SdH) oscillation was observed and the sheet electron concentration calculated from the period of the SdH oscillation agreed closely with the value ($=6.9 \times 10^{11}$ cm$^{-2}$) obtained by Hall measurement.

Persistent photoconductivity was observed for all SD heterostructures fabricated here. Fig.6 shows the relation between 2DEG mobility and sheet electron concentration, when sheet electron concentration was increased as a result of exposure to light at 5K. 2DEG mobility increased with increasing $N_s$ and reached a maximum value of 180000 cm$^2$/V sec at $N_s = 7.8 \times 10^{11}$ cm$^{-2}$. Beyond this point, 2DEG mobility decreased.

(4) Conclusion

A leak-proof MOCVD growth apparatus capable of producing rapid changes in gas composition over the wafer has been constructed and suitable growth conditions for SD GaAs/Al$_{0.3}$Ga$_{0.7}$As heterostructures having high 2DEG mobility have been obtained. It is shown that the total impurity concentration in the undoped Al$_{0.3}$Ga$_{0.7}$As spacer layer has a remarkable effect on 2DEG mobility. A 2DEG mobility of 150000 cm$^2$/V sec at 4.2K was obtained. In order to obtain further increase in 2DEG mobility, the use of organometallic compounds such as triethyl gallium and triethyl aluminum in place of TMG and TMA is considered. This is because it has been reported that the use of triethyl gallium results in less carbon incorporation into GaAs than the use of TMG.
