1. Introduction

With a continuous shrinkage of the memory cell size in eDRAMs, MIM (Metal-Insulator-Metal) structures have received a lot of attention to obtain an enough storage capacitance. [1, 2] Even if the MIM structures are applied to memory cells, very thin capacitor dielectric films are still required to keep the data storage characteristics beyond 90-nm technology node. In addition, it is important to avoid damages for the capacitor dielectric film during the top-electrode formation in order to maintain a low leakage current across the dielectric film. [3]

In this paper, we propose a new TiN-CVD method for the top-electrode formation, which consists of several sets of TiN deposition and in-situ NH₃ annealing at a low temperature to achieve excellent properties in TiN/Ta₂O₅/TiN structures.

2. Experimental

Figure 1 shows the fabrication process of TiN/Ta₂O₅/TiN capacitors used in this paper. After the formation of Ta₂O₅ dielectric films, TiN films were deposited from TiCl₄ and NH₃ as top-electrodes, ranging from 350 to 500 °C in temperature, from 5 to 20 nm in thickness. In-situ annealing in NH₃ ambient was carried out to reduce the residual Cl in the deposited TiN films.

The details of TiN-CVD deposition sequences are shown in Fig. 2; (a) is the divided deposition method demonstrated in this paper, and (b) is the conventional method as a control process.

The properties of MIM capacitors were investigated by I-V measurements. The surface morphology of the CVD-TiN films was observed using SEM.

3. Result and Discussion

Figure 3 shows the dependence of the capacitor leakage current on the deposition temperature of TiN in the case of the conventional method. The conventional TiN-CVD process at 450 °C can suppress the leakage current, while those over 475 °C increase the current.

Figure 4 shows the leakage current of MIM capacitors as a function of the applied voltage for the several NH₃ annealing temperatures. The leakage current in the case of NH₃ annealing at 450 °C is the same as that without NH₃ annealing. Over 500 °C, the leakage current increases as the annealing temperature increases. This result indicates that the degradation of the Ta₂O₅ film is caused by the reaction with NH₃. We suggest that the increase in leakage current at higher deposition temperatures, shown in Fig. 3, is also due to the reaction of the Ta₂O₅ film with NH₃ or products from NH₃. Therefore, the TiN-CVD process below 450 °C would be necessary for the suppression of the Ta₂O₅ degradation and for keeping the low leakage current during the TiN deposition with TiCl₄ and NH₃.

Although the TiN deposition below 450 °C can suppress the leakage current, a lot of anomalous growth substances are produced on the TiN film surfaces, as shown in Fig. 5. The size is about 50 to 100 nm. The anomalous growth substance is increased for the lower deposition temperature, as shown in Fig. 6. Since such large anomalous growth substances could be the killer defects, the CVD-TiN films deposited below 450 °C are not applicable to ULSI fabrication processes. Figure 7 shows the relationship between the leakage current and the density of anomalous growth substance. This result indicates that it is difficult to reduce the leakage current without the anomalous growth substances using the conventional TiN-CVD process.

Figure 8 shows the SEM images of the surface morphology of 5-nm TiN films deposited at 450 and 350 °C. It should be noted that the anomalous growth does not occur at both temperatures in such thin TiN films.

However, as shown in Fig. 9, the leakage current increases as the TiN film thickness becomes less than 10 nm in the case of the conventional deposition at 450 °C. We propose that this increase in current is attributed to the degradation of the Ta₂O₅ films due to the reaction with NH₃, since the large amount of NH₃ penetrates through such thin TiN films. Therefore, there is no process window in the conventional method for keeping the low leakage current without the anomalous growth.

The penetration of NH₃ through thin TiN films should be reduced in lower-temperature processes. In addition, as indicated in Fig. 8, the anomalous growth does not occur on the 5-nm TiN film formed at 350 °C. Therefore we have investigated the effect of the deposition of thin TiN films and the NH₃ anneal at 350 °C on the leakage current across the Ta₂O₅ films. Figure 10 shows the leakage current as a function of the process temperature in the case of the divided TiN deposition method, in which several sets of the thin TiN deposition and the NH₃ anneal were repeated, as depicted in Fig. 2(a). The low level of the leakage current is successfully accomplished by using the divided deposition of TiN at 350 °C. Figure 11 shows the SEM image of the surface morphology of the 20-nm TiN film deposited by the divided method at 350 °C. No anomalous growth is observed. Thus we have demonstrated that the divided deposition method at 350 °C provides the low leakage current without the anomalous growth.

4. Conclusions

For the TiN/Ta₂O₅/TiN MIM capacitor structure, we demonstrated that the leakage current could be kept low by using the divided TiN deposition process at 350 °C, which is compatible with the suppression of the anomalous growth. The divided TiN-CVD deposition process at low temperature is expected as a promising method for the top-electrode formation for a MIM structure beyond the 90-nm node.
