1. Introduction

Silicon-on-insulator (SOI) photodetector has advantages of high-speed operation and large voltage gain per electric charge because of the low parasitic capacitances. However, due to the small thickness for light absorption, the sensitivity of SOI photodetector is usually not high. In order to solve this problem, we have proposed a gold (Au) line-and-space (L/S) grating that can be applied to SOI metal-oxide-semiconductor (MOS) p-n photodiode [1], and the enhanced light sensitivity by the grating is experimentally demonstrated for the first time [2]. In this paper, dependence on grating materials, such as Au, silver (Ag) and aluminum (Al) is numerically investigated by finite difference time domain (FDTD) method. It is found that the light sensitivity can be enhanced by any grating material, and the peak wavelengths are almost unchanged as long as the grating periods are the same. These features are very unique, because the grating material can be selected from these materials considering productivity, compatibility with applications, and so on. For example, Al is widely used in the process of large-scale integrated circuits (LSIs). Thus, the study on material dependence will be of great use.

2. Device Structure

Figure 1 shows the proposed SOI-MOS p-n photodiode with binary metal L/S grating and the definition of incident light polarization for the grating direction. As grating materials, Au, Ag and Al are chosen. In the case of Au and Ag, 5-nm-thick Ti is inserted as an adhesion layer between grating and SiO₂. The incident light enters normally to the photodiode surface. The thickness of the top SiO₂, which is called as gate oxide, is optimized for 700-nm-wavelength and TM-polarized light. In SOI layer, the lateral resonance of waveguide modes can be excited by the diffracted light from the grating. Figure 2 shows the top view of one of the fabricated devices with p' active area of \( L = W = 50 \mu m \).

3. Results and Discussions

Figure 3 shows the simulated and measured spectroscopic external quantum efficiency (QE) for TM polarization in SOI-MOS photodiode with and without Au/Ti grating. The SOI thickness \( t_{SOI} \) is 95 nm. Comparing with simulated results, maximum value is decreased, and full width at half maximum (FWHM) is expanded, for the grating period in the measured results. These values are affected at least by the resolution of the spectrometer (8 nm) in our light illumination system. Nevertheless, especially for grating period \( p = 300 \) nm, the external QE can be enhanced to 25%, and its enhancement factor is 8.3. Figure 5 shows the material dependence of L/S grating. The SOI thickness \( t_{SOI} \) is 100 nm. The peak heights of external QE are almost unchanged independent of the grating material. In order to clarify this reason, Fig. 5 compares the relationships of peak wavelengths of external QE vs. grating period \( p \) in Fig. 4, and the propagation wavelengths \( \lambda_{g} \) of lateral waveguide modes in SOI layer vs. free-space wavelength. Propagation wavelengths are obtained by calculating eigenvalues of symmetrical slab waveguide composed of 100-nm-thick Si core and infinite-thick SiO₂ clads [3]. These two relationships coincide well indicating that the incident light is efficiently coupled to the waveguide mode and absorbed in SOI when \( p \) is equal to \( \lambda_{g} \).

4. Conclusions

SOI-MOS p-n photodiodes with L/S grating of Au, Ag, and Al have been numerically and experimentally investigated. It has been shown that any grating of these materials could enhance the light sensitivity of SOI-MOS p-n photodiode for TM-polarized light. Also, the reason why the peak wavelength is determined only by the grating period regardless of the material has been clarified. Thus, considering the compatibilities with the application, grating material can be selected from Au, Ag, or Al. Especially, Al grating for enhanced light sensitivity is of great use considering the popularity of the material in LSI processing.
